KEYWORDS
Blepharoplasty; Eyelid correction; Eyelid surgery; Functional outcomes

Abstract
Objective: Various functional outcomes after upper blepharoplasty are reported in the literature. We systematically reviewed the literature to assess the objective and subjective functional effects of upper blepharoplasty.

Methods: After a systematic search of four search engines (Pubmed, Embase, Cinahl and Cochraine), any study on objective and subjective (patient reported) functional outcome after upper blepharoplasty was subjected to a quality assessment for possible inclusion in the review. The intervention was defined as a solitary surgical upper blepharoplasty containing the removal of skin, with or without the removal of a strip of orbicularis oculi muscle and/or upper orbital fat. Eligible studies were randomized controlled trials, controlled trials, cohort studies and case series (n ≥ 10).

Results: A total of 3525 studies were assessed, of which 28 studies were included in this systematic review. Favorable outcomes after an upper blepharoplasty were reported and included enlarged visual field, enhanced quality of life related to fewer headaches and improved vision. Furthermore, sensitivity of the eyelids decreased, with differences in recovery. Outcomes for eyebrow height, astigmatism, contrast sensitivity and eyelid kinematics were not consistent between the studies. No meta-analysis could be performed due to the limited scope of included studies and the great variety in outcomes and blepharoplasty techniques.

Conclusions: Upper blepharoplasty is accompanied by a great variety of beneficial functional outcomes including an increased visual field and improvement in headache- and vision-related...
quality of life. Further research is needed, especially where results are conflicting (effects on eye dryness and eyebrow height) and/or the data are limited (contrast sensitivity, astigmatism). © 2018 British Association of Plastic, Reconstructive and Aesthetic Surgeons. Introduction

Blepharoplasty of the upper eyelids is one of the most commonly performed surgical procedures in aesthetic surgery. This technique is used to correct redundant skin, also known as dermatochalasis, and subcutaneous tissue in the upper eyelid.

Dermatochalasis can lead to an aesthetically poor appearance and a variety of functional symptoms. These functional symptoms include difficulty in elevating the upper eyelids, limited peripheral vision by blocking the field of view, periorbital discomfort and dry eyes. Dermatochalasis may also lead to overuse of the occipitofrontalis muscles, e.g., in patients with ptosis, resulting in tension-type headache.

Surgical removal of the redundant skin of the upper eyelid may improve several aspects, such as field of view, eye dryness and quality of life. In addition, upper blepharoplasty may lead to a decline of the electrical activity of the frontalis muscles, indicating a tension reduction of these muscles, and may subsequently lead to relief of tension headache.

Unfortunately, few studies have been published that assessed objective functional outcomes of an upper blepharoplasty. Moreover, these studies reported different, and occasionally conflicting, outcomes. Comparing outcomes between studies is also difficult because some studies involve the combination of blepharoplasty with more extensive procedures such as ptosis surgery and because different blepharoplasty techniques were used in different studies. Finally, the existing randomized controlled studies on blepharoplasty often focused on the aesthetic outcomes and not on functional outcomes. To enhance our understanding of this topic, we performed a systematic review assessing the objectively determined functional outcomes of upper blepharoplasty.
Methods

A systematic review protocol was established before the beginning of the review process to minimize the potential for bias. The systematic review follows the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines.

Search methods for identification of studies

We searched the following electronic databases: PubMed, Embase, Cinahl and Cochrane Central Register of controlled trials. Keywords for the search included “blepharoplasty”, “upper”, “eyelids/surgery”, “eyelid reconstruction”, “eyelid correction”, “blepharochalasis”, “dermatochalasis” and “eye lid surgery” (for the full list of keywords, see Appendix 1). In addition, reference lists of the full-text papers were screened for relevant studies missed in the search.

Eligibility criteria

Studies were eligible if surgical upper blepharoplasty was carried out and outcome variables were assessed before and after surgery. Studies that included adult patients (18 years and older) were included, without further age restrictions. There were no gender or ethnicity restrictions. The intervention in the eligible studies consisted of a solitary surgical upper blepharoplasty containing the removal of skin, with or without the removal of a strip of orbicularis oculi muscle and/or upper orbital fat.

Outcome variables included any functional objective outcome, such as peripheral vision, as well as self-reported functional outcomes such as eye strain, satisfaction and quality of life (QoL). Eligible studies were randomized controlled trials, controlled trials, cohort studies and case series with 10 or more participants. Case series with fewer than 10 participants and case reports were excluded. No language restrictions were applied. Studies were also excluded when a procedure other than the surgical upper blepharoplasty was used or when other surgical procedures were performed as adjunctive to the upper blepharoplasty (e.g., ‘double eyelid’ operation, ‘Asian blepharoplasty’, surgical creation of a supratarsal crease, lower blepharoplasty).

Study selection

Duplicates were removed by one observer (MH). Further study selection was performed by two observers (MH & MC) and was conducted in two stages: First, the titles and abstracts were assessed according to the inclusion criteria. The selection process was tested by applying the inclusion criteria to a sample of papers (papers that were excluded) to check whether inclusion criteria could be interpreted reliably. Second, the full text was assessed if studies appeared to meet the inclusion criteria or if a decision on inclusion could not be made based on the title and/or abstract alone. The quality assessment was also piloted by applying the MINORS criteria and by filling in the data extraction form on a small sample of papers. Subsequently, two observers independently performed the study selection. Disagreement (in 74 papers) was discussed during a consensus meeting. In case of a persistent disagreement, a third independent expert (JJ) was available to make a binding decision. However, no persistent disagreements were present after the consensus meeting. An overview of the study selection is shown in Appendix 2.

Inter-observer agreement

After the assessment of titles and abstracts, the agreed observations between the two observers (MH & MC) was 97.9% and after the consensus meeting 100%. Cohen’s kappa was 1.0 after the consensus meeting.

Quality assessment

The methodological quality of the included studies was assessed by two independent observers (MH & MC) using the methodological index for non-randomized studies (MINORS) criteria. The MINORS criteria were used to provide a quality score for the included studies; this was not part of the selection process.

Data extraction

One observer (MH) included studies after full-text quality assessment. Subsequently, the data extraction was carried out on the previously piloted data extraction form. One observer (MH) extracted the data and the second observer (MC) checked the data independently for accuracy and completeness.

Data synthesis

The included studies comprised a range of outcomes, therefore data could not be pooled and no meta-analysis was possible. In the results, we reported only a narrative synthesis of the findings from the included studies.

Results and discussion

Study selection

A total of 3525 studies (after removal of duplicates) were screened, of which 86 studies were assessed in full text for eligibility. Finally, 28 studies remained for qualitative synthesis. The first search was performed on the 6th of February 2017, and updated on the 24th of December 2017. This resulted in two additional studies, which were also included. The search of reference lists did not result in additional inclusions (see flowchart).
Study characteristics

Studies were categorized based on functional outcome: dry eyes, upper visual field, eyebrow height, shape of cornea, sensitivity of upper eyelid skin, contrast sensitivity, eyelid kinematics and quality of life. The mean (± standard deviation) MINORS score for the included studies in this systematic review was 10 ± 3. Table 1 provides an overview of the studies selected for review. Below, we describe a synthesis and discuss the included studies.

Dry eyes

Dry eyes were assessed by a variety of diagnostic tests and by scoring subjective complaints. A few studies evaluated whether dry eyes could be alleviated, worsened or provoked by blepharoplasty and whether the method of blepharoplasty makes any difference. One study evaluated subjective dry eye symptoms, such as burning, itching, redness and foreign body sensation of the eyes. 12 In symptomatic patients who underwent a blepharoplasty, the symptoms decreased significantly. Another study evaluated subjective and several objective dry eye parameters, but did not report a significant effect of blepharoplasty based on these parameters. 13 Another study mentioned that a blepharoplasty had no effect on dry eye scores assessed with a questionnaire. 14 The ocular surface scores (fluorescein staining) were reduced 30 days after surgery, while later on (after 90 days), the scores did not significantly differ from baseline. This was also the case for Schirmer test scores, tear break-up time and rose Bengal scores at any point in time. 15 Thus, a blepharoplasty may potentially alleviate subjective complaints of dry eyes, but at least does not induce or worsen dry eye symptoms.

When interpreting the results reported in the previous paragraph, it has to be mentioned that dry eyes are difficult to evaluate. Dry eye symptoms have a complex and multifactorial aetiology as well as that there is no single definitive diagnostic test to identify or classify the severity of dry eye disease. Dysfunction of any component of the lacrimal functional unit, such as decreased tear production, increased evaporative loss and changes in drainage, can result in dry eye symptoms. Subjective dry eye complaints were reported to be alleviated by surgery, but this observation was often not supported by objective tests, such as Schirmer test, Break-up time and Rose Bengal scores. 14,15 It was shown, however, that the inflammatory reaction and ocular surface scores reduced after surgery. 14,15 Thus, based on our systematic review, we are unable to draw a clear conclusion about the effect that patients can expect from a blepharoplasty. Some authors suggested that a reduced inflammatory reaction, a changes blink mechanism or more confidence of patients about their appearance might underlie this beneficial effect. 13 Other authors have suggested that by compromising the integrity of the orbicularis muscle, dry eyes may even worsen. 15 The study on eyelid kinematics that was included in this systematic review did not report significant changes in blink dynamics despite resection of orbicularis muscle during upper blepharoplasty.

Upper visual field

Redundant skin and subcutaneous tissue in the upper eyelid may cause limitations in the upper visual field. Three out of seven eligible studies reported a significant reduction of visual field defects after blepharoplasty. 2,3,19 The other four studies reported a tendency for improvement of visual field. 4,5,9,26 Thus, resection of the excess eyelid skin will extend the visual field. The possible lowering of the eyebrow, discussed in the next section, does not seem to affect this increase.

Eyebrow height

In patients with dermatochalasis, obstruction of the superior visual field may result in compensatory frontalis muscle action to lift the eyebrows. When in these cases a blepharoplasty is performed, the frontalis muscles theoretically can loose the neurological feedback from the brain to continue to elevate the eyebrow, which may result in lowering of the brows. Nine studies assessed the occurrence of secondary brow ptosis after upper blepharoplasty.

Five studies reported a significant eyebrow descent after surgery. The descent was found in the whole eyebrow, 21,22 the middle portion in males 23 and was most pronounced in the lateral part of the eyebrow. 24,25 Four other studies did not report a significant effect on eyebrow descent after upper blepharoplasty. 24,25,26,27 One of these was the study by Dar et al., 26 who evaluated the effect of upper blepharoplasty on eyebrow height while accounting for ocular dominance, fat excision, change in MRD1 (Margin Reflex Distance 1) and degree of dermatochalasis. MRD1 is the distance between the light reflex on the patient’s cornea to the upper eyelid margin during primary position of gaze. Multivariable comparison provided insufficient evidence to show that MRD1, ocular dominance or dermatochalasis were significantly associated with the mean percentage of change in eyebrow height at all positions with or without fat excision. Another study addressed ocular dominance specifically. 27 Involuntary unilateral eyebrow elevation may lead to the perception of residual excess skin in the contralateral upper eyelid in a subset of patients who have undergone upper eyelid blepharoplasty. The latter study assessed the relationship between asymmetric eyebrow elevation and ocular dominance and concluded that involuntary asymmetric eyebrow elevation and ocular dominance are significantly associated. Summarizing, data on eyebrow height after blepharoplasty are inconsistent.

The inconsistencies of the studies reported may be the result of various factors including surgical technique, scar formation, frontal muscle activity and ocular dominance. Most of the studies involving surgical technique, i.e. a technique in which surgeons excised herniated fat and/or removed part of the orbicularis muscle, reported a significant decrease of eyebrow height. 21,24 Only the study of Dar et al. 26 did not report that significant changes in eyebrow height occurred. Unfortunately, no eligible studies were available in which the effect of a skin-only blepharoplasty on eyebrow height was evaluated.

There might be a relationship between asymmetric eyebrow elevation and ocular dominance. Shah et al. 30 pointed

** The study of Rogers et al (2012) is described in the ‘perimetry’ and the ‘contrast sensitivity’-section.
out that asymmetric eyebrow elevation may lead to the perception of residual excess skin in the contralateral upper eyelid in a subset of patients who have undergone upper eyelid blepharoplasty. According to the authors, if unrecognized this asymmetry may result in the surgical overcorrection of the contralateral eyelid.10

Shape of cornea

Removal of excess upper eyelid skin and raising the eyelid with blepharoplasty may lead to redistribution of the pressure applied by the lids over the cornea and consequently to changes in corneal shape. This change can be documented with corneal topography. Also, the pressure of excess skin and prolapsed fat may cause alterations in corneal curvature. This could change corneal refraction, astigmatism and may cause blurred vision. Two studies reported a significant change in corneal astigmatism after upper blepharoplasty11,12: increased astigmatism in the first and third month after surgery11 and a change in mean astigmatism after blepharoplasty. When fat pads are also reduced, a more pronounced change in astigmatism was observed as compared to skin-only excision (0.21D vs. 0.06D).12 The third study measured many ocular variables but the only parameter that was significantly different from the preoperative value was the keratometric value of the steepest meridian in one group of patients.13

The extent to which patient notice the above mentioned changes remains unclear. Visual changes of 0.50D or less are noticed only by patients whose normal activities of daily living require a high standard of visual performance. It is worth noting that astigmatic changes may also occur after ptosis surgery14–16 and tend to regress after 6-12 months.14–16

Sensitivity of the upper eyelid skin

During blepharoplasty, the sensory innervation of the upper eyelid skin can be damaged, resulting in paraesthesia or anaesthesia of the pre-tarsal skin. Only two studies on this aspect met our inclusion criteria; both reported significantly decreased sensitivity after upper blepharoplasty, but different findings about recovery over time. One study reported full recovery of sensitivity after 6 months (perception of touch, temperature, pressure and pain),17 whereas the other study reported only partial recovery after 6-7 months (pressure).18

Thus, decreased sensitivity of the upper eyelid skin may follow an upper blepharoplasty. However, the included studies did not agree about the recovery after upper blepharoplasty. Since the follow-up in the included studies was only six to seven months, it would be interesting to prolong the follow-up in future studies to see the outcome after a longer time period.

Contrast sensitivity

Patients may note brighter vision after upper blepharoplasty, which may be caused by the removal of redundant skin. Rogers et al.19 evaluated whether this surgery also has an effect on contrast sensitivity. Contrast sensitivity is defined as the ability to detect luminance contrast. A reduction can have a considerable effect on functions such as night driving and reading. Postoperative contrast sensitivity indeed increased significantly in this study (p = 0.00002).

Another excluded study evaluated the cause of increased contrast sensitivity and improved visual acuity after upper eyelid surgery.20 The hypothesis in this study was that increases in contrast sensitivity are the result of changes in corneal topography, high-order aberrations (subtle and complex refractive errors) or lash ptosis. However, no changes in corneal topography after upper eyelid surgery were observed. Kim et al.21 concluded that reduction of high-order aberrations increase contrast sensitivity and allow more accurate vision. The authors explained that overhanging skin and lash ptosis block light entering the eye and cause diffraction. The study concluded that the changes in contrast sensitivity are caused by changes in ocular high-order aberrations and by the degree of lash ptosis after surgery. The actual practical visual benefit of this increase in contrast sensitivity is difficult to qualify. The authors stated that the effect of upper eyelid blepharoplasty is approximately equivalent to half the effect of cataract surgery on contrast sensitivity.20

Eyelid kinematics

Abell et al.22 evaluated the effect of upper blepharoplasty on blink dynamics. This was done to test the hypothesis that partial orbicularis oculi removal causes alterations in blinking. Also, altered blinking is a possible cause of dry eye symptoms after blepharoplasty. The blink dynamics were evaluated by a modified scleral search coil technique. Despite muscle resection, no significant changes in blink dynamics were found.

Quality of life aspects

Bahceci-Simsek23 conducted a prospective study among 108 patients who underwent upper eyelid blepharoplasty. They evaluated changes in headache-related quality of life (QoL) after blepharoplasty and used the Headache Impact Test 6 (HIT-6). The results indicated that blepharoplasty can improve headache-related QoL. Another study used the Abbreviated National Eye Institute Visual Function Questionnaire (NEIVFQ9) as a tool for assessing vision-related QoL in patients with dermatomalalisis.11 This study found a significant increase in visual function in dermatomalalisis patients after surgery. Finally, Jacobsen et al.9 described the functional and psychological impact of upper blepharoplasty on patients. They also reported improvement. Thus, all self-reported outcomes, including headache and heavy eyelid feeling, improved after blepharoplasty.

As mentioned before, upper blepharoplasty may lead to a decline in the electrical activity of the frontalis muscles, which in turn may lead to a relief of tension headache.12 An excluded study in our review (only 9 patients evaluated) supported this presumption in that study every HIT-6 question improved significantly.18 Future research should study
this relationship between blepharoplasty, frontal muscle activity and headache more in detail.

Limitations of the literature and further research

One limitation is that most included studies in this systematic review were dominated by female participants. Therefore, the conclusions in those studies cannot be automatically generalized to male participants.

Another limitation in comparing the outcomes of the included studies is the use of a variety of surgical techniques of upper blepharoplasty. In some articles the exact method of blepharoplasty was not even described in detail. In many procedures, excess skin is removed together with a strip of orbicularis oculi muscle, sometimes combined with excision or redistribution of fat from the medial and central fat compartments. The rationale for both muscle and fat resection along with skin is unclear. It is also, unclear whether the septum should be coagulated during surgery. One theory supports the importance of saving the orbicularis oculi muscle and orbital fat because this preserves the fullness of the peri orbital region, thus preventing the hollow orbit of the aged.\textsuperscript{13,41–44} Another theory is that dry eye complaints are prevented by preserving the orbicularis oculi muscle.\textsuperscript{45} Although blepharoplasty is performed very frequently in aesthetic surgery, there is no consensus about which procedure is most suited for a blepharoplasty and for which patient. In the review of Hoornije et al.,\textsuperscript{46} a lack of consensus about what is to be done with the orbicularis oculi muscle in upper eyelid blepharoplasty is demonstrated.

In theory, left-right comparative studies may result in more evidence-based outcomes. The study of Kiang et al.\textsuperscript{43} conducted a left-right comparative study where patients were treated with skin-only blepharoplasty on one side and a combined skin-muscle removal on the other side. They concluded that muscle-sparing blepharoplasty may induce less sluggish eyelid closure, less lagophthalmos and less dry eye disease. In this systematic review their study was excluded due to the performance (on a part of the participants) of a tarsal fixation to improve the supratarsal crease definition or to create one, which was one of the exclusion criteria. Another split-face pilot study was performed to evaluate the aesthetic differences between skin-only blepharoplasty and blepharoplasty with stripping of the orbicularis oculi muscle. A trend favouring the skin-only side was present, but no difference between the techniques was significant.\textsuperscript{47}

Authors’ conclusions

Several positive functional effects may be expected after upper blepharoplasty, such as an increased visual field and improvement in headache- and vision-related QoL. Further research is needed, especially where results are conflicting (eye dryness, eye brow height) and/or in cases of limited scientific data (contrast sensitivity, astigmatism, frontalis muscle activity).
